Pre-Processing + Linear Regression

**MESTRADO EM ENGENHARIA DE TELECOMUNICAÇÕES E
INFORMÁTICA**

**Inteligência Artificial para as Telecomunicações
2025/2026**

Objectives

- The primary goal of this task is **to create a comprehensive and efficient workflow** tailored specifically for pre-processing the dataset to develop a **logistic regression model** for predicting survival on the Titanic dataset .
- The **pre-processing phase** is critical for **preparing raw** data, ensuring it is **clean, well-structured, and suitable** for further analysis or modeling.

Pre-processing

- **Data Cleaning:** Identifying and handling missing values, correcting inconsistencies, and removing duplicates to ensure data quality.
- **Data Transformation:** Applying necessary transformations, such as scaling, normalization, and encoding categorical variables, to standardize the dataset.
- **Data Integration:** Combining or merging multiple datasets to create a unified dataset that is ready for analysis.
- **Feature Engineering and Selection:** Creating new features, selecting important ones, or reducing dimensionality to improve model performance and computational efficiency.

Dataset

12 attributes

PassengerId: An identification number for each passenger;

Survived: This is the target variable (0 = The passenger did not survive, 1 = The passenger survived);

Pclass: Passenger class (1 = Upper class, 2 = Middle class, 3 = Lower class);

Name: Full name of the passenger;

Sex: Gender of the passenger (male or female);

Age: Age of the passenger in years (with some missing values);

SibSp: Number of siblings/spouses aboard the Titanic;

Parch: Number of parents/children aboard the Titanic;

Ticket: Ticket number;

Fare: The ticket fare the passenger paid;

Cabin: Cabin number (with many missing values);

Embarked: Port of embarkation (with C = Cherbourg, Q = Queenstown, S = Southampton).

Pre-processed workflow

KNIME Analytics Platform

Goal:

- Understand **Logistic Regression**
- Develop a **Logistic Regression model** capable of predicting the "*Survived*" feature within the Titanic dataset.
- Analyze the measures used to **evaluate the model**

Logistic Regression

Logistic Regression is a statistical model used for binary **classification** tasks, where the goal is to predict the probability of **one of two outcomes**, i.e., "yes" or "no". Instead of fitting a straight line like in linear regression, logistic regression applies a logistic function to produce a probability between 0 and 1.

To develop a logistic regression model for predicting survival on the Titanic dataset, we can use logistic regression to determine the probability that a passenger survived or did not survive based on several features such as age, sex, passenger class, and more.

Here's how:

- **Binary Classification:** Since the "Survived" feature in the Titanic dataset is binary (1 for survived, 0 for did not survive), logistic regression is well-suited for modeling this kind of outcome.
- **Probability Prediction:** Logistic regression will estimate the probability of each passenger surviving based on their characteristics. This probability output is between 0 and 1, thanks to the logistic function, which maps inputs into a probability.
- **Decision Boundary:** By setting a threshold (often 0.5), we can use this probability to classify each passenger as likely to survive (1) or not (0).
- **Feature Influence:** The logistic regression model will assign coefficients to each input feature (i.e., age, sex, class) to indicate how they impact the likelihood of survival. Positive coefficients increase the probability of survival, while negative ones decrease it.

Open the workflow from the previous class, press Shift and, with your mouse, hover through all nodes until the ***Partitioning*** node. After that, press **Ctrl+C**.

Create a **new workflow** and press **Ctrl+V** to paste all the **selected** nodes.

To successfully implement a Logistic Regression model, some **changes** need to be made in the *pre-processing* nodes that we just pasted.

To improve the logistic regression model:

- **delete** the initial **Rule Engine** node that maps the values of the Sex attribute to binary values (i.e., male as 1 and female as 0).
- Instead, include this attribute in the **One to Many** node, which **encodes categorical** attributes as **separate binary** columns.

Mapping Sex to binary values (0 or 1) in the Rule Engine node can create an unintended assumption that one category has more significance than the other. By using one-hot encoding, each category (i.e., Male and Female) is represented independently, removing any notion of ordering or preference between the categories. Additionally, in logistic regression, one-hot encoding makes it easier to interpret the effect of each category independently, as each encoded category gets its own coefficient. This way, we can see the individual impact of being male or female on the survival prediction.

S Pclass
S Sex

☐ Enforce inclusion

☒ Remove included columns from output

After removing the first Rule Engine node, open the configuration panel of the **One to Many** node and **include** the **Sex** attribute.

After running the node, you can see that **two** new columns were generated for each value of the Sex attribute: a column for "**female**" and a column for "**male**", each containing **binary values**.

Third Number (intege...	First Number (intege...	Second Number (intege...	male Number (intege...	female Number (intege...
1	0	0	1	0
0	1	0	0	1
1	0	0	0	1
0	1	0	0	1

Delete the **Math Formula** node that derives the ***FamilySize*** variable.

Logistic regression is a linear model that can **struggle with complexity**. Including too many variables increases the dimensionality of the dataset and can complicate the decision boundary the model is trying to learn.

Thus, simplifying the model by removing FamilySize can lead to better performance, as the logistic regression can better approximate the true relationship between features and the target variable.

In its place, we will be inserting the **Number to String** node.

In the Node Repository, search for the **Number to String** node. Insert it **between the Normalizer node and the Partitioning node**.

The Number to String node will be applied to the **Survived** attribute to **convert** it from a **numeric** type to a **string** type.

Using "0" and "1" (the values of the Survived attribute) as strings allows us to treat them as categorical labels, ensuring that logistic regression interprets them as **distinct classes rather than numeric values**. This helps avoid any unintended mathematical operations and clarifies to the model that these values represent categories (survived or not) rather than a continuum.

Open the Number to String node's configuration panel.

Include the Survived attribute and run the node.

In the Node Repository, search for the **Logistic Regression Learner** node.

Connect the **output** port of the **Partitioning** node to the **input** port of the **Logistic Regression Learner** node.

The Logistic Regression Learner node in KNIME trains a logistic regression model on labeled data, optimizing feature coefficients to predict the probability of a binary outcome based on input features.

Open the configuration panel of the
Logistic Regression Learner node.

Make sure the **target** column is **Survived**!

Run the node.

The screenshot shows the configuration panel for the Logistic Regression Learner node. The panel is divided into several sections: Target, Solver, and Feature selection. The Target section shows the target column set to 'Survived' and the reference category set to '1'. The Solver section shows the solver set to 'Stochastic average gradient'. The Feature selection section shows the 'Manual Selection' radio button selected, with the 'Exclude' list empty and the 'Include' list containing 'Age', 'SibSp', 'Parch', 'Fare', 'Third', 'First', 'Second', and 'male'. The 'Enforce exclusion' radio button is selected in the 'Exclude' section, and the 'Enforce inclusion' radio button is selected in the 'Include' section. The 'Use order from column domain' checkbox is unchecked at the bottom.

Settings | Advanced | Flow Variables | Job Manager Selection | Memory Policy

Target

Target column: Survived

Reference category:

☐ Use order from target column domain (only relevant for output representation)

Solver

Select solver:

Feature selection

☒ Manual Selection ☐ Wildcard/Regex Selection ☐ Type Selection

Exclude

No columns in this list

☒ Enforce exclusion

Include

☐ Enforce inclusion

☐ Use order from column domain (applies only to nominal columns). First value is chosen as reference for dummy variables.

In the Node Repository, search for the **Logistic Regression Predictor** node.

Connect the **output** port of the **Logistic Regression Learner** node to the input port of the **Logistic Regression Predictor** node. Connect the **second output** port of the **Partitioning** node to the **second input** port of the **Logistic Regression Predictor** node.

The Logistic Regression Predictor node in KNIME uses the trained logistic regression model to generate predicted probabilities and class labels for new data, determining the likelihood of each input belonging to the target classes.

To assess the performance of the model, in the Node Repository, search for the **Scorer** node.

Connect the **output** port of the **Logistic Regression Predictor** node to the **input** port of the **Scorer** node.

Open the configuration panel of the Scorer node.

Select **Prediction (Survived)** as the **First Column** and **Survived** as the **Second Column**.

Run the node.

Click on the magnifying glass icon of the Scorer node to access the **performance metrics**.

Let's start by analyzing the **confusion matrix**:

- **True Negatives (0 predicted as 0)**: 101 passengers who did not survive were correctly classified as not surviving.
- **False Positives (0 predicted as 1)**: 16 passengers who did not survive were incorrectly classified as surviving.
- **False Negatives (1 predicted as 0)**: 17 passengers who survived were incorrectly classified as not surviving.
- **True Positives (1 predicted as 1)**: 45 passengers who survived were correctly classified as surviving.

Confusion Matrix - 3:51 - Scorer

File Hilite

Prediction ...	0	1
0	101	16
1	17	45

Correct classified: 146 Wrong classified: 33
Accuracy: 81.564% Error: 18.436%
Cohen's kappa (κ): 0.591%

In terms of **performance metrics**:

- **Accuracy:** The model achieved an accuracy of 81.56%, meaning it correctly classified about 82% of the passengers.
- **Error Rate:** The model has an error rate of 18.44%, representing the percentage of passengers that were misclassified.
- **Cohen's Kappa (K):** 0.591 indicates moderate to substantial agreement between the predicted and actual classifications, adjusting for chance agreement. A higher K value (closer to 1) would indicate stronger predictive power.

Confusion Matrix - 3:51 - Scorer

File Hilite

Prediction ...	0	1
0	101	16
1	17	45

Correct classified: 146
Accuracy: 81.564%
Cohen's kappa (κ): 0.591%

Wrong classified: 33
Error: 18.436%

The model generally **performs well**, with a **relatively high accuracy** and a moderate Cohen's Kappa.

However, there is still a **noticeable misclassification rate**, particularly with 17 passengers who actually survived but were predicted not to survive. Improving feature selection, tuning the model, or using additional preprocessing steps could help reduce these errors, especially the false negatives, to improve the model's sensitivity to passengers who survived.

If you hover the Logistic Regression Learner, you see a danger sign with the following message:

“The algorithm did not reach convergence after the specified number of epochs. Setting the epoch limit higher might result in a better model.”

A single iteration through the training dataset is called an epoch.

This message from the Logistic Regression Learner node in KNIME indicates that **the algorithm was unable to reach convergence within the set number of epochs, or iterations, that it performs during the training process.**

In logistic regression, convergence means that the model's parameters have stabilized and are no longer changing significantly from one iteration to the next.

Increasing the epoch limit allows the algorithm more time to find the best fit for the data. This adjustment can help the model achieve better convergence, potentially improving classification accuracy and reducing error rates. In this case, raising the epoch limit could lead to a more accurate logistic regression model that may perform better in classifying passengers as "Survived" or "Not Survived."

Open the Logistic Regression Learner node's configuration panel.

Select the **Advanced** option and change the number of epochs from **100** to **200**.

The screenshot shows the configuration panel for the Logistic Regression Learner node, specifically the 'Advanced' tab. The panel has five tabs: 'Settings', 'Advanced', 'Flow Variables', 'Job Manager Selection', and 'Memory Policy'. The 'Advanced' tab is selected. It contains two sections: 'Solver options' and 'Termination conditions'. In the 'Solver options' section, there are two checked checkboxes: 'Perform calculations lazily (more memory expensive but often faster)' and 'Calculate statistics for coefficients'. In the 'Termination conditions' section, the 'Maximal number of epochs' is set to 200 (via a spinner control) and the 'Epsilon' is set to 1.0E-5.

Settings Advanced Flow Variables Job Manager Selection Memory Policy

Solver options

- ☒ Perform calculations lazily (more memory expensive but often faster)
- ☒ Calculate statistics for coefficients

Termination conditions

Maximal number of epochs: 200

Epsilon: 1.0E-5

Run all the remaining nodes.

The danger sign has been resolved, and the model has reached convergence with consistent performance metrics, that correspond to the same obtained as previously. This can be due to the fact that some models may have limited capacity to learn complex relationships in the data. Increasing epochs won't enhance performance if the model architecture cannot capture the necessary complexity.
